ABSTRACT

Continual labeling of training examples is a costly task in supervised learning. Active learning strategies mitigate this cost by identifying unlabeled data that are considered the most useful for training a predictive model. However, sample selection via active learning may lead to an exploitation-exploration dilemma. In online settings, profitable items can be neglected when uncertain items are annotated instead. To illustrate this dilemma, we study a human-in-the-loop customs selection scenario where an AI-based system supports customs officers by providing a set of imports to be inspected. If the inspected items are fraud, officers levy extra duties, and these items will be used as additional training data for the next iterations. Inspecting highly suspicious items will inevitably lead to additional customs revenue, yet they may not give any extra knowledge to customs officers. On the other hand, inspecting uncertain items will help customs officers to acquire new knowledge, which will be used as supplementary training resources to update their selection systems. Through years of customs selection simulation, we show that some exploration is needed to cope with the domain shift, and our hybrid strategy of selecting fraud and uncertain items will eventually outperform the performance of the exploitation strategy.

1 INTRODUCTION

Suppose you are the head of the customs office for developing an AI-based selection system and manage officers working on-site who inspect goods based on the system recommendation. Let us picture a scenario where trade traffic is increasing quickly over the years, and new importers emerge in fraudulent trades and deceive the system with sophisticated tactics. Over time, field officers start to notice the algorithm's degrading performance and request to update the detection algorithm. Adopting an entirely new algorithm will lose the domain knowledge gained over decades, but continuing

the old model will suffer from declining fraud detection rate. In this case, what can be done?

As illustrated in this story, machine learning models in online prediction settings must adapt well to input changes, which is a challenge known as the domain shift [22]. In the context of customs operations, the list of countries procuring a particular product will change over time, and some importers can declare an unknown product. Even a well-trained machine learning model can fall into the trap of confirmation bias and may not capture these changes. Particularly for situations in which manual labeling is expensive, it can be challenging to make significant changes to the model's working logic.

To mitigate this problem, active learning has been proposed to provide a guideline on how to interactively query a user to annotate data points to catch up with an unknown concept. In the classical active learning setting, the model encourages to query data to clear uncertainty and secure diversity. However, in a real-world online prediction scenario, queried data are often subjected to evaluation. This means the system needs to be profitable while it is securing knowledge for the future. So the learning model cannot fully follow the exploration principles of active learning. To describe the problem, we introduce a case study in which customs administrations maintain an AI-based selection model to support officers' collecting duties.

Figure 1 depicts a customs clearance process. To trade goods across borders, importers need to specify the trade items' information in import declaration forms. We hypothesize that a trade selection model plays a role in determining and screening which items should be inspected by customs officers. Officers determine the authenticity of the items. If the items are fraud, additional duties are granted accordingly. Due to astronomical trade volume, not all items are subject to inspection. The amount of additional tariffs that can be secured differs by items. Besides, it is challenging to

calculate the potential benefits of examining uncertain items. Once the items are inspected, the selection model's parameters can be updated using newly inspected items as additional training samples. Overall, devising a selection strategy that can maximize the current performance while securing its knowledge for the future is crucial for maintaining the customs selection system in the long run.

The current paper proposes a hybrid selection strategy designed to gain long-term performance benefits for fraud-detection. By leveraging the concept of exploration, our model keeps up to date against domain shifts, while the concept of exploitation maintains the high-quality precision for detecting fraudulent transactions. As an alternative to the random exploration used by customs [13], we proposed gATE methodology built upon *state-of-the-art* active learning approach [2]. gATE is designed to select the most informative samples in a diverse way to capture the dynamically changing traits of trade flows. Tested on real trade data from three African countries, we empirically demonstrate that the proposed hybrid model outperforms state-of-the-art exploitation models in detecting frauds as well as in securing revenue.

The main contributions of this paper are as follows, we:

- Defined a customs selection setting in which the system requires to follow new trends adaptively and secure profits.
- Proposed a new hybrid selection strategy that builds on the stateof-the-art exploration and exploitation strategies.
- Examined the long-term benefit of exploration strategy on realistic simulation setting.
- Released a code for simulating customs selection considering the needs from customs administration.

2 RELATED WORK

Customs fraud detection. Earlier research on customs fraud detection has focused on rule-based or random selection algorithms [13, 19]. However, these classical methods are known to be brittle and are hard to maintain. The application of machine learning in customs administration has been a closed task primarily due to data's proprietary nature. Several recent studies have shown the use of off-the-shelf machine learning techniques like XGBoost, SVM [6, 27]. State-of-the-art is the DATE (Dual Attentive Tree-aware Embedding) model, which employs the transaction-level embeddings in customs fraud detection [17]. This model gives interpretable decisions that can be checked by the customs officers and achieve high revenue in the collected tax.

However, an optimized algorithm is expected to face performance degradation over a longitudinal time period due to limited adaptability to uncertainty, diversity, and the domain shift in customs traffic. This exploration versus exploitation dilemma is what we try to tackle in this paper.

Active learning. Active learning is one of the promising domains in machine learning. It enables an algorithm to elicit ground truth labels for uncertain data instances and enhance its performance [12, 24]. This learning technique is utilized for training the model to deal with high dimensional data [11], to offer long-term benefits [7, 20], to select appropriate data instances to speed the model training [25], or to train the model with limited budgets [29] effectively.

One research proposes a way to measure the informativeness of given samples [10, 15]. This approach tries to collect as much information as possible to boost the training by choosing the samples it finds uncertain [14, 28]. Another research line focuses on improving diversity by collecting diverse samples representing the overall data distribution. Diversity based algorithms include region-based active learning [8, 9] and core-set based approach [23]. Recent research work has also become focused on concurrent inclusion of both uncertainty and diversity aspects [2, 30].

There are two main differences between existing active learning approaches and our customs fraud detection settings. First, active learning research usually assumes offline setting [18, 26], including the state-of-the-art BADGE algorithm [2]. This assumption is impractical and far from real-world customs fraud detection scenario. Even if some of the algorithms set the training dataset label as dynamic, the test dataset in the offline setting remains static. Over time, in the customs fraud detection setting, the evaluation dataset's domain can become outdated.

Secondly, our customs fraud detection setting does not have any explicit test data for evaluation, and the performance evaluation of the selected item is done during the annotation process. Since the queried fraudulent items (i.e., exploitation) and uncertain items for acquiring new information (i.e., exploration) share the same budget for annotations, the balancing between exploration and exploitation becomes crucial. This constrained optimization setting is not common in conventional active learning techniques.

Recent studies have come up with interpolating exploration and exploitation strategy in the context of active learning, as pure exploration or exploitation is not applicable to test datasets that are prone to domain shifts [16, 21].

Randomized algorithm. In customs fraud detection scenarios, one can also assume the presence of fraudsters that would act as an adaptive adversary of our model. Research literature involving online learning algorithm [4, 5] has shown that randomness in the selection process improves the competitiveness of an algorithm under an online setting ski-rental problem, as a randomized algorithm is more robust against adaptive online adversary model. In this light, we additionally introduce randomness to our sampling strategy.

Having shown the biases involved in interpreting fact-checking messages, we now revisit the experiment assumptions to discuss potential limitations. We also present findings from small-group user interviews, which helps us better interpret the survey study.

3 CUSTOMS SELECTION

The customs administration aims to detect fraudulent transactions and maximize the tax revenue from illicit trades — this is the customs fraud detection problem. Given an import trade flow \mathcal{T} , the main goal is to predict both the fraud score y^{cls} and the raised revenue y^{rev} obtainable by inspecting transactions \mathbf{x} .

However, as transaction volume is huge, customs administration cannot practically screen all suspicious transactions. While some customs offices had conduct 100% manual inspection, this has become costly and time-consuming with astronomically growing trade volume. Furthermore, most recently, customs offices are compelled to cut down on many intensive operations in light of the health pandemic and social distancing. There is a growing need

Table 1: Notations used throughout the paper.

Symbol	Definition
\mathcal{T}	Import trade flow
f	Customs selection strategy
r	Inspection (selection) rate
\mathcal{B}_t	Items that is received at timestamp <i>t</i>
$\mathcal{B}_t^S(f)$	Items selected by strategy f at timestamp t , $\mathcal{B}_t^S(f) \subset \mathcal{B}_t$
$\mathcal{B}_{t}^{F}(\cdot)$	Items selected as frauds, $\mathcal{B}_t^F(\cdot) \subset \mathcal{B}_t^S(\cdot)$
$\mathcal{B}_t^U(\cdot)$	Items selected as uncertain, $\mathcal{B}_t^U(\cdot) \subset \mathcal{B}_t^S(\cdot)$
\mathbf{x}_i	<i>i</i> -th transaction from the selected batch \mathcal{B}_t^S
y_i^{cls}	binary variable denoting item \mathbf{x}_i is fraud
y_i^{rev}	non-negative value denoting item \mathbf{x}_i 's revenue
X_t	Training data for timestamp $t, X_t = X_0 + \bigcup_{k=1}^{t-1} \mathcal{B}_k^S(\cdot)$
m	Evaluation metric for $\mathcal{B}_t^S(f)$, (e.g., Revenue@k%)

to develop an efficient selection strategy that can identify suspicious trades and increase revenue. We formulate the customs trade selection problem as follows:

Given a trade flow \mathcal{T} , can we construct a selection strategy f that maximizes the detection of fraudulent transactions and the associated tax revenue?

Trade flow \mathcal{T} consists of the online stream of trade records, which include importer id and HS code of the goods. With time, the dynamics and distribution of fraud transactions change.

Active Selection for Online Setting

Current research on customs fraud detection mainly concentrates on the static setting, in which a model is trained from large training batches and deployed for fraud detection without updates. This approach assumes that the training and test data in trade flow \mathcal{T} would be drawn from the same distribution. However, in an online setting, fraud transactions' distribution changes over time, and traditional approaches will fail to detect novel frauds.

This paper builds a customs selection model that best performs in an online setting, namely Active Customs Selection. Unlike the customs fraud detection problem that only requires selecting the maximum fraudulent transactions for every timestamp, the active customs selection problem also requires the selection strategy to help the model update and adapt for new types of fraud. All inspected items can bring additional information, but choosing items that aid the model performance with the selection strategy to improve the model's future performance is crucial in this problem.

We can formally define the active customs selection problem as follows: At each time t, given a batch of items \mathcal{B}_t from the trade flow \mathcal{T} , based on a strategy f trained with X_t , customs officers will select a batch of items \mathcal{B}_t^S to inspect and add into the training set manually. The goal is to devise a strategy f_m that maximizes the precision and revenue in the long-term future (let say from timestamp t_0 onward).

$$f_m = \underset{f}{\operatorname{argmax}} \frac{1}{T - t_0 + 1} \sum_{t = t_0}^{T} m(\mathcal{B}_t^s(f))$$

where *m* is the evaluation metric (precision or revenue for fraud transactions). Table 1 lists some frequently used notations throughout the paper, and the main training process for fraud detection with active customs selection is described in Algorithm 1.

Algorithm 1 Active Customs Selection

Input: Inspection rate r%, historical data X_0 , unlabeled datastream of new items in each timestamp \mathcal{B}_t , number of timestamps T

Output: Items for inspection in each timestamp t

Initialize the training data as the historical data $X_1 = X_0$

for t = 1, 2, 3, ...T **do**

Obtain the batch of new items \mathcal{B}_t ;

Get the inspection budget $k_t = |\mathcal{B}_t| \times r\%$;

Train the strategy f with X_t ;

Based on the trained strategy f, select a set of k_t items $\mathcal{B}_t^S(f)$ for manual inspection;

Get the ground-truth annotation $(\mathbf{x}_i, y_i^{cls}, y_i^{rev})$ for each item $\mathbf{x}_i \in \mathcal{B}_t^S$ after manual inspection;

Add the newly annotated items into the training data:

 $X_{t+1} = X_t \cup \mathcal{B}_t^S;$

end

HYBRID SELECTION STRATEGY

The quality of the active customs selection problem depends on a good selection strategy f. We propose a new strategy that combines two approaches: **exploitation** and **exploration**. The exploitation approach selects the most likely fraudulent and highly profitable items to secure the short-term revenue for customs administration. On the other hand, the exploration approach selects uncertain items at the risk of an instant revenue loss, potentially detecting more of novel fraud patterns in the future. The algorithm operates by mixing these two components and aims to produce performance improvements in the long run on highly imbalanced customs datasets with a small initial training set. Figure 2 illustrates the overall framework of the proposed model.

4.1 Exploitation Strategy

The state-of-the-art algorithm to detect illicit transactions and predict the raised revenue in a customs setting is the DATE model [17]. It is a tree-enhanced dual-attentive model to optimize dual objectives (illicit transaction classification and revenue prediction). We leverage the predicted fraud score of DATE for our exploitation strategy. At each timestamp, we update the DATE model and select the most suspicious items as per the inspection budget (see Algorithm 2).

Algorithm 2 Exploiting suspicious items by DATE

Input: Training set X_t , items received \mathcal{B}_t , inspection budget k_t **Output:** A batch of selected items \mathcal{B}_t^S

Train the DATE model using training set X_t ;

Perform prediction on \mathcal{B}_t , get the predicted annotation

 $(\mathbf{x}_i, \hat{y}_i^{cls}, \hat{y}_i^{rev})$ for each item $\mathbf{x}_i \in \mathcal{B}_t$;

Obtain the set \mathcal{B}_t^S of k_t items with highest fraud score \hat{y}_i^{cls} ;

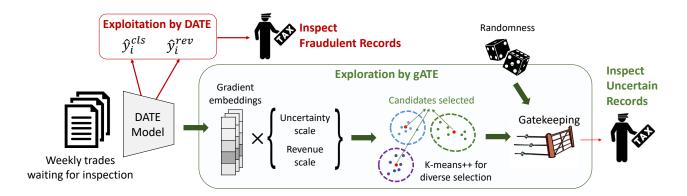

Figure 2: Illustration of the hybrid selection framework. The state-of-the-art exploitation model DATE first computes whether the input trade records are fraud or not. Then, the bATE algorithm computes back-propagation with pseudo-labels to generate a gradient embedding and re-scale it with its uncertainty and revenue. Then, k-means++ algorithm is applied to select diverse yet uncertain samples for inspection. Considering the DATE performance, a gating unit decides to use which items to explore.

4.2 Exploration Strategy

The exploitation strategy selects the more familiar and highly suspicious transactions for inspection; therefore, it tends to underperform over time when trade patterns gradually change. Instead, our hybrid strategy chooses to add a small portion of new and uncertain trades as a learning sample in the training data, which gradually affects the model's future prediction performance. Since fraud types are always evolving, the model performance might drop over time. We propose an exploration strategy to select uncertain trade items, with additional consideration on diversity and revenue to resolve these issues.

4.2.1 Exploration in light of uncertainty and diversity. One option for detecting new types of fraud is to use the network's uncertainty as a query strategy. Selecting items for which the model is least confident can provide more information on similar new observations. However, this strategy can create a unfavorable scenario where newer labelled data does not include diverse transaction types and labels for identical type of transactions keep on accumulating. In this light, we include the concept of diversity along with uncertainty in our selection strategy, i.e., choosing as diverse samples as possible for stable and fast exploration [2, 18]. By taking into account uncertainty and diversity concepts, we adopt gradient embedding and k-means++ initialization from BADGE [2] in our exploitation model DATE to figure out which trades should be queried for inspection . Detailed implementation of each concept is described in turn below.

Uncertainty. If a sample generates a large gradient loss and, consequently, a large parameter update, the item potentially contains useful information. This means the magnitude of gradient embedding reflects the uncertainty of the model on samples. With this motivation, we aim to choose trade flows with uncertainty using magnitude of gradient embedding. At time t, for each trade item \mathbf{x}_i in \mathcal{B}_t , the illicitness classifier h_θ from the DATE model return its fraud score \hat{y}_i^{cls} which reflects the illicit class of y_i^{cls} .

$$h_{\theta}(\mathbf{x}_i) = \sigma(W \cdot z_{\phi}(\mathbf{x}_i)) \tag{1}$$

where W is a weight matrix that projects the output z_ϕ of DATE illicitness class space.

The gradient embedding g_{x_i} is the gradient of the loss function with respect to W and sample x_i . Since the received data points are unlabeled, we predict the pseudo label \hat{c}_i by the fraud score with threshold 0.5 (i.e. $\hat{c} = \mathbb{1}(\hat{y}_i^{cls} \geq 0.5)$). This pseudo label is used to calculate loss, resulting in the gradient embedding described in [2]:

$$g_{x_i}^c = (p_i^c - \mathbb{1}(\hat{c}_i = c)) \cdot z_{\phi}(x_i)$$
 (2)

where $c \in \{0,1\}$ corresponding to 2 classes and p_i^c is the predicted probability for class c; $p_i^{c=0} = 1 - \hat{y}_i^{cls}$ and $p_i^{c=1} = \hat{y}_i^{cls}$.

Diversity. We create a batch of query items based on gradient embedding with k-means++ algorithm [1] in connection with the diversity. We obtain the set \mathcal{B}^s_t of k centroids that are sampled with probability proportional to the distance of the nearest sets to take diversity into account. Samples with small gradients are also unlikely to be chosen, as the distance between them is small. Thus, gradient embedding with k means++ seeding tends to choose a large gradient sample diversely.

4.2.2 Scale the uncertainty and revenue effect. Furthermore, to induce the algorithm to select more uncertain and high-revenue items, we introduce extra weights to amplify the effect of uncertainty and revenue. The weights, called uncertainty scale and revenue scale, adjust the probability of samples to be chosen by resizing their gradient embedding vectors.

Uncertainty scale. We magnify the impact of uncertain items by quantifying the model's ability to calibrate an item. We give each item an *uncertainty score*¹ (Eq. 3) such that the score implies the magnitude of model's uncertainty about the item. In this paper, we use a fraud score \hat{y}_i^{cls} from the DATE model as a measure of item uncertainty. We give a higher scale of uncertainty unc_i if a fraud score \hat{y}_i^{cls} is close to the midpoint 0.5, the uncertainty score unc_i is defined as:

$$unc_i = -1.8 \times |\hat{y}_i^{cls} - 0.5| + 1.$$
 (3)

 $^{^{1}}$ A metric ranging in from 0.1 to 1. The smallest value is 0.1 (instead of 0) for computation stability.

Revenue scale. Active learning in customs operation requires additional consideration, as revenue needs to be collected as customs duty. Maximizing customs duty is one of top priorities of customs authorities. Therefore, we further amplify the gradient embedding by the DATE model's predicted revenue \hat{y}_i^{rev} . The distribution of the amount of customs duty is right-skewed, so we take the log of the predicted revenue (Eq. 4). We can define a final scale factor S_i of \mathbf{x}_i as

$$S_i = unc_i \cdot log(\hat{y}_i^{rev} + k). \tag{4}$$

As a result, gradient embeddings $g_{x_i}^c$ becomes

$$g_{x_i}^c = |S_i| \cdot (p_i^c - \mathbb{1}(\hat{c} = c)) \cdot z_{\phi}(\mathbf{x}_i).$$
 (5)

k is a constant for computation stability. We name the algorithm which is covered from Section 4.2 to 4.2.2 as bATE, denoting the fusion of BADGE strategy [2] and DATE model [17].

4.2.3 Gatekeeping. In practise, some importers might commit frauds by analyzing and reverse engineering the model's prediction patterns. We can call them adaptive adversaries of the model. In this situation, randomness is known to improve the robustness and competitiveness of the online algorithm [4, 5]. With this motivation, we additionally introduce randomness to our sampling strategy. Using a validation performance of DATE model, we operate a gatekeeper. If the Rev@n% is higher than a predefined value of θ , the bATE exploration algorithm is used. Otherwise, if the DATE models' outputs are highly unreliable, those inputs can be considered an attack, thereby facilitating the random selecting of items for inspection.

To alleviate this discussed issues, we propose the final exploration strategy gATE. The gATE algorithm can be formally represented in Algorithm 3:

Algorithm 3 Exploring unknown items by gATE

Input: Current training set X_t , items received \mathcal{B}_t , inspection budget k_t

Output: A batch of selected items \mathcal{B}_t^S

Train the DATE model using training set X_t ;

Get the Rev@n% from validation set;

if $Rev@n\% > \theta$ then

Perform prediction on \mathcal{B}_t , get the predicted annotation

 $(\mathbf{x}_i, \hat{y}_i^{cls}, \hat{y}_i^{rev})$ for each item $\mathbf{x}_i \in \mathcal{B}_t$;

Calculate the gradient embedding g_{x_i} (Eq. 5);

Obtain the set \mathcal{B}_t^S of k_t items by k-means++ initialization;

else

Obtain the set \mathcal{B}_t^S of k_t items by random sampling;

end

4.3 Hybrid Strategy

The exploitation-only model can lead to confirmation bias. With a model trained only on the historical data and given the domain shift in customs datasets, the model tends to be unreliable from outliers. However, a pure exploration strategy cannot secure customs revenue and is unrealistic in the customs setting. Hence, we consider a balance between the two to achieve both short-term and long-term performance. We propose a *hybrid selection strategy* under the

Table 2: Statistics of the datasets

Datasets	Country M	Country N	Country T	
Periods	Jan 13-Dec 16	Jan 13-Dec 17	Jan 15-Dec 19	
# imports	0.42M	1.93M	4.17M	
# importers	41K	165K	133K	
# tariff codes	1.9K	6.0K	13.4K	
Illicit rate	1.64%	4.12%	8.16%	

online active learning setting that includes two main approaches: *exploitation* and *exploration* by utilizing DATE and gATE.

In detail, for selecting items that will potentially enhance the model's performance, we design a strategy gATE for exploration (§4.2.1–4.2.3). We used the DATE strategy that exploits historical knowledge to generate the highest possible revenue [17] and guarantees short-term revenue. The final selection is done by the hybrid approach which balances between the gATE and DATE strategies. This algorithm can be formally represented in Algorithm 4.

Algorithm 4 Hybrid Selection using DATE and gATE

Input: Current training set X_t , items received \mathcal{B}_t , inspection budget k_t

Output: A batch of selected items \mathcal{B}_t^S

Train the DATE model using training set X_t ;

Calculate the inspection budget $k_1 = r_1 \cdot |k_t|$, $k_2 = r_2 \cdot |k_t|$ for each strategy based on a predefined (normalized) ratio $r_1 : r_2$; Obtain the set \mathcal{B}_t^F of k_1 items by exploitation (DATE) strategy; Obtain the set \mathcal{B}_t^U of k_2 items by exploration (gATE) strategy; Return the set $\mathcal{B}_t^S = \mathcal{B}_t^F \cup \mathcal{B}_t^U$

5 EXPERIMENTS

5.1 Evaluation Settings

5.1.1 Datasets. For experiments, we employed transaction-level import declarations of three countries in Africa. The import data fields include numeric variables such as item price, weight, quantity, and categorical variables such as tariff code, importer ID, country code, and received office. Each country had slightly different data variables, that were preprocessed by following the previous study [17]. Note that these three customs were subjected to detailed inspection (i,e., achieving nearly 100% inspection rate). But this practise is not sustainable and the customs offices of the these countries plan to reduce the inspection rate in the future. Due to the manual inspection, the transaction labels and charged tariffs are accurately labeled in these logs at the single-goods level. Table 2 and Figure 3 depict the statistics of the data we have utilized.

5.1.2 Long-term simulation setting. The experiment aims to find the best selection strategy to maintain the customs selection model in the long run. Therefore, we simulate an environment where a selection model is deployed and maintained for multiple years².

²Previous works split data into training and testing sets on the temporal basis and compared the performance of diverse machine learning models [17, 27]. However, the algorithm's performance in static prediction state cannot depict the model's performance in the real setting when the model is deployed.

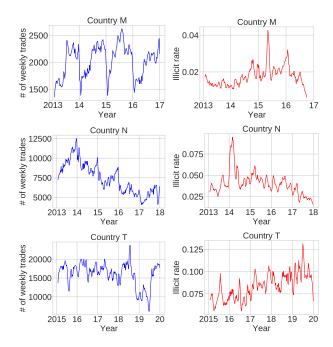

Figure 3: Number of weekly trades and illicit rate

Given that one month's worth of training data is available, the system receives import declarations and selects a batch of items to inspect during the week. A selection model is trained based on a predefined strategy, and the most recent four weeks' worth of data is used for validating the model. By using inspection results, the model is updated every week. To simulate a scenario of data providers who are willing to reduce the inspection rate gradually, we implemented several methods to decay the inspection rate by time. In this experiment, we set the target inspection rate as 10%. Starting with 100% inspection, we used linear decaying policy by reducing the inspection rate by 10% per each week. Once the target inspection rate is reached, the system maintains the inspection rate for the remaining period.³

5.1.3 Evaluation metrics. We evaluate selection strategies' performance by referring to two metrics used in previous work [17]; Precision@n% and Revenue@n%. Since we are dealing with an online simulation setting where illicit rate changes each week, we divided each metric's value by the oracle's performance.

- Norm-Precision@n%: Pre@n% divided by the performance measured by oracle. Pre@n% explains how many transactions are illicit, among the top n% of transactions.
- Norm-Revenue@n%: Rev@n% divided by the performance measured by oracle. Rev@n% is the total revenue in top n% transactions identified by a model divided by the total revenue among all transactions. This metric explains how much customs duties can be generated from the top n% of transactions than the revenue generated by inspecting the entire transactions. In the following sections, we mainly used this metric to report the results.

For example, if the system with 5% inspection rate is operating on the environment with 2% illicit rate, Pre@5% and Rev@5% of the oracle would be 0.4 and 1, respectively. Let us consider the deployed selection strategy achieves the Pre@5% value of 0.39. To avoid any potential interpretation bias caused by small absolute value, we divide 0.39 by the performance upper-bounds of 0.4, which results 0.975 of Norm-Pre@5%.

Note: Because we are given a fully-labeled dataset, we can measure these metrics with ground truth information. For countries that are already maintaining a low inspection rate, these metrics can be modified by conditioning on their observable goods.

5.2 When Exploitation Strategy Fails

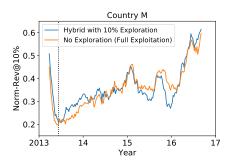

To answer the question raised in the introduction, we first compare the performance between the pure-exploitation strategy DATE and the partial-exploitation strategy with some random exploration; we can call it as a naive hybrid strategy. The naive hybrid strategy uses DATE and random on a scale of 9 to 1. Surprisingly, we observe that a pure-exploitation strategy can crash sometimes. Figure 4(c) illustrates the customs simulation in country T. The performance of the state-of-the-art DATE exploitation strategy unexpectedly drops as time goes, but the performance of the hybrid strategy remains stable. It is worth noting that the performance of drops significantly over time despite the increasing size of the training data. This confirms that the items chosen for inspection are uninformative and evidence a domain shift in country T's trade pattern. We can also deduce that the exploration strategy items significantly boost the performance of the exploitation strategy. Considering that the randomly selected items may only affect 1% of the total revenue on average, the performance boost arises from inspecting unknown items.

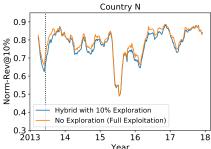

To back up the claim, we explored whether there exists a domain shift in the trading pattern of country T. Figure 5 describes the ratio of each import country for an item with commodity code starting with 620 in 2015, 2017, and 2019. There are significant trade rates and domain shifts observed in the top three countries that imported items. Country A, B used to be where the item is imported the most, but starting from 2017, the shifting in import countries sharply changes, and country C become a dominant source country for imported goods.

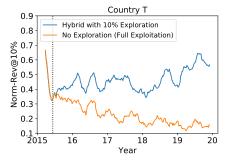

5.3 When Exploitation Strategy Does Not Fail

Is it a common phenomenon that the performance of the exploitation strategy decreases over time? We check again to see if these behaviors are common across all datasets. Reassuringly, we also observe that the fully-exploitation strategy does not always fail. In Figure 4(a)–(b), we can see the results obtained from country M and country N. For those countries, maintaining the strategy of screening the most fraudulent items is still valid. However, when we compare the averaged performance between the exploitation strategy and the hybrid strategy, we can also find that the former does not beat the latter (Norm-Rev@10%, Exploitation vs. Hybrid: 54.0% vs. 57.7% for country M, 86.0% vs. 86.1% for country N; a moving average of the last 13 weeks). It is interesting to see that inspecting a set of random items is even better than inspecting reasonably fraudulent items with high \hat{y}^{cls} values (top 9-10%) for maintaining a customs selection system in the long run. So, how

³In countries where the daily import declaration's size is larger, it would be possible to update a selection strategy every day, and more reliable results could be obtained even with a shorter period.

- (a) In country M, the performances of both strategies increase over time.
- (b) In country N, and the performances of both strategies high and stable.
- (c) In country T, the exploitation strategy failed, unlike a hybrid model.

Figure 4: For some case, the performance of an exploitation strategy DATE drops as time goes, but the performance of hybrid strategies remains stable even for cases in which exploitation strategy fails. This shows that exploration is necessary for maintaining a selection system in a long run.

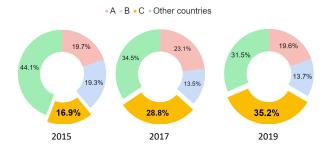

Figure 5: An example of domain shift in country T: The source country for commodity X (HS-code starting with 620) is rapidly changing over the years.

much will performance improve if the better exploration strategy is used rather than random? We measured the performance of the proposed exploration strategies.

5.4 Finding the Best Exploration Strategy

A natural question arises that what would be the best strategies for exploration. We first compared the performance of pure exploration strategies, assuming a need to build a system that wants to explore. This experimental setting may not be very realistic for advanced countries that maintain clean enough histories to train a model and would like to exploit their knowledge. However, this experiment is necessary for customs administration where there are not enough import histories available, so they want to fit the model as quickly as possible. This experimental setting is also widely used in the active learning community [2, 18], for comparing performances between the static pool-based active learning algorithms. We performed experiments with four exploration strategies, including our proposed model designed in Section 4.2.

- Random [13]: Known to be used as an exploration strategy to detect novel frauds in the production system of some countries.
- BADGE [2]: State-of-the-art active learning approach by selecting items considering uncertainty and diversity.

- bATE: Exploring by considering predicted revenue as well as item uncertainty and item diversity.
- gATE: Strategically decide the exploration strategy between random and bATE, depending on the performance of the base model.

Figure 6 shows the 13-week moving average performance of exploration strategies. The result shows that three advanced strategies BADGE, bATE, and gATE outperform random strategy in a large margin. bATE is the top-performing strategy in country M and T, and gATE performs the best in country N. Considering that the performance of the fully-exploitation strategy reaches up to 0.9 in country N (Figure 4b), the performance of the fully-exploration strategy itself is not impressive. It can be seen that the exploration strategy and exploitation strategy are needed together to guarantee the reliable performance of the customs selection system.

5.5 Best Exploration Strategy for Hybrid Model

Next, we compare the performance of these exploration strategies by applying with an exploitation strategy. Following Section 5.2-5.3, each hybrid strategies select 90% of the item by DATE, and remaining 10% of the item is selected by four exploration strategies. We also compare them with DATE to show the long-term sustainability of hybrid strategies.

Figure 7 show the performance of hybrid models with different exploration strategies. First, we can see that all hybrid strategies outperform a fully-exploitation strategy with some margin. For the T dataset, where a staggering decline of exploitation strategy performance is recorded, our hybrid strategy performs exceptionally stable, and the model is getting better towards the end. For the other two datasets, even though the DATE model for exploitation remains effective, the 10% trade-off for exploration does not hurt the overall performance but even slightly outperforms the exploitation algorithm. This proves our initial claim that even if we give up some inspection of suspicious items, we can guarantee similar performance by learning new patterns from the unknown. Second, the hybrid model's performance with a random exploration strategy is comparable to the hybrid model with advanced exploration strategies.

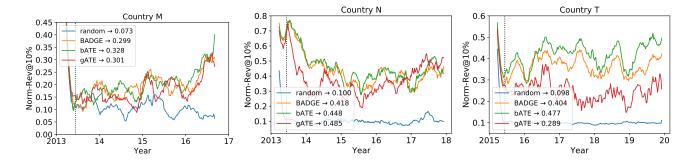

Figure 6: Performance of the advanced exploration strategy outperforms the random selection when only exploration strategy is used. Note that the random selection is widely used in many customs offices.

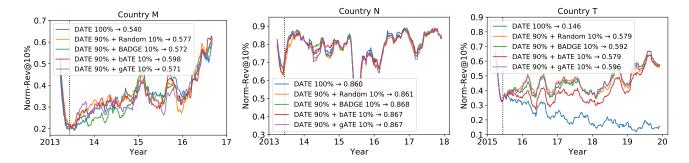

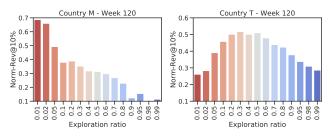

Figure 7: Combined with DATE, there is no significant difference between the performance of hybrid strategies.

(a) The model performs the best with 1% of exploration.

(b) The model performs the best with 30% of exploration.

Figure 8: Best performing exploration ratio differs by data. In the case which the exploitation strategy does not work well, increasing an exploration ratio helps (Country T).

In practice, we encourage customs administration to start with a random strategy since it has almost no computation cost. The customs selection model will be improved even more robustly without using additional computing power. Third, advanced exploration strategies can help to raise the whole hybrid model to the best performance. This is shown from the result that DATE+bATE accomplished 2.1% higher revenue than DATE+random in country M. However, it is noteworthy that the best exploration algorithm bATE does not always contribute the most to the hybrid strategy. For further results, please refer to Table 3, and Figure 9 to 10.

6 CONCLUDING REMARK

This paper investigates the exploitation-exploration dilemma, where the indicators of annotated samples are key criteria for evaluation. One such example can be found in customs tax fraud detection, where customs officers need to decide which new cargo to inspect (i.e., an exploration strategy) while keeping the history of existing illicit trades (i.e., an exploitation strategy). We herein present an active learning-based model that efficiently combines the exploration and exploitation strategies. Our numerical evaluation, based on multi-year transaction logs, brings insights for practical guidelines for setting model parameters in the context of customs screening systems.

To facilitate the proposed approach in the customs administrations, the model code is open-sourced. Currently, it supports diverse exploitation and exploration strategies with a variety of tunable parameters ranging from models to simulation settings, so that users would be able to confirm whether our proposed work is wellsuited for their data. There are two directions that this work can be extended.

• Determining the right balance for exploration and exploration: Currently, the ratio between exploration and exploitation is set empirically. The model performance is sensitive to this ratio and the performance numbers vary depending on the dataset (Figure 8). An adaptive algorithm to select this ratio will manage this trade-off better. RP1 algorithm [3] leverages an online learning mechanism with the exponential weight framework to dynamically tune this ratio, which could be applicable in our model.

 Higher performance can be achieved by using richer information from a set of uninspected imports by incorporating a semisupervised learning strategy in our framework. Building a set of augmented customs data and learning from it would be a key challenge for devising a semi-supervised learning model.
